Draft version February 2, 2008

ABSTRACT

This paper presents a new technique for reconstructing the spatial distributions of hydrogen, temperature and metal abundance of a galaxy cluster. These quantities are worked out from the X-ray spectrum, modeled starting from few analytical functions describing their spatial distributions. These functions depend upon some parameters, determined by fitting the model to the observed spectrum. We have implemented this technique as a new model in the *XSPEC* software analysis package. We describe the details of the method, and apply it to work out the structure of the cluster A1795. We combine the observation of three satellites, exploiting the high spatial resolution of *Chandra* for the cluster core, the wide collecting area of *XMM-Newton* for the intermediate regions and the large field of view of *Beppo-SAX* for the outer regions. We also make a threefold test on the validity and precision of our method by *i*) comparing its results with those from a geometrical deprojection, *ii*) examining the spectral residuals at different radii of the cluster and *iii*) reprojecting the unfolded profiles and comparing them directly to the measured quantities. Our analytical method yields the parameters defining the spatial functions directly from the spectra. Their explicit knowledge allows a straightforward derivation of other indirect physical quantities like the gravitating mass, as well as a fast and easy estimate of the profiles uncertainties.

Subject headings: galaxies: clusters: general cooling flows — intergalactic medium — galaxies: clusters: individual (A1795) — methods: data analysis — X-rays: galaxies: clusters

1. INTRODUCTION

A deep insight into the early life of our Universe is provided by the largest and youngest virialized structures: clusters of galaxies. A valuable tool to fathom the physics and the structure of these objects is their X-ray emission. This stems from the hot (1 – 10 keV) and optically thin plasma (also known as intra-cluster medium, or ICM) which makes up some 10 – 20% of their total mass. This rarefied plasma is so hot because it has to develop a pressure strong enough to maintain itself in quasi-hydrostatic equilibrium within the gravitational well of the dark matter. The ICM is transparent and allows to see deeply, down to the very core of the cluster. This transparency has also a drawback: photons born at different depths mix up along the same lines of sight, and a direct use of the spectral information to investigate in three dimensions the physical conditions of a cluster is impossible. The first step is necessarily a *deprojection* of the X-ray spectrum, which provides the deconvolved three-dimensional profiles of density, temperature and metal abundance. From these fundamental direct quantities others may follow, like the distribution of heavy elements or the cluster gravitating mass.

This paper describes a novel deprojection technique we have implemented as a new model in the *XSPEC* software package for the analysis of X-ray spectra. The fundamentals of the theory are recalled in Section 2. In Section 3 we apply them to build up our deprojection model. In Section 4 we make a specific example by de-

projecting the nearby cluster A1795. A comparison is also made between our results and those from another deprojection technique. In Section 5 the methods to test the solidity of our deprojection are reviewed. Finally, in Section 6 we show how the result of our analytical deprojection may help to derive other physical variables of cosmological interest.

2. THE SPECTRUM OF AN OPTICALLY THIN SPHERE OF PLASMA

In this Section we briefly review the fundamental formulae for the flux from the diffuse medium of a cluster of galaxies. This is approximated as a spherically symmetric cloud of optically thin plasma located at redshift z . The observed photon flux from a source subtending the solid angle Ω is

$$\mathcal{F}_E = \int_{\Omega} d\Omega I_E/E, \quad (1)$$

where I_E is the specific brightness in the observer's rest frame, expressed in terms of the spectral energy E . The specific brightness is obtained by integrating the spectral emissivity $j_{E'}$ along an optical path across the source. If this passes at a distance b from the emission center, the hypothesis of spherical symmetry yields

$$I'_{E'} = \int dl j_{E'} = 2 \int_b^{\infty} dr \frac{r j_{E'}(r)}{\sqrt{r^2 - b^2}}, \quad (2)$$

where all primed quantities refer to the cluster rest frame, so $E = E'/(1 + z)$ is the redshifted spectral energy. The quantity I_E/E^3 is invariant along the path of a light ray (see e.g. Rybicki & Lightman 1979), thus the emitted and observed specific brightnesses are related by $I'_{E'}/E'^3 = I_E/E^3$. Taking this into account, Equation (2) can be substituted into (1), where the integration

³ Osservatorio Astronomico di Brera, via Bianchi 46, 22055 Merate (LC), Italy.

over the solid angle can be usefully rewritten in terms of the projected size of the source. If the emitting region is located at the angular distance D_A and is seen as an annulus bounded by the projected rims $b_{\min}$ and $b_{\max}$, Equation (1) becomes

$$\mathcal{F}_E = \frac{4\pi}{D_A^2 (1+z)^2} \int_{b_{\min}}^{b_{\max}} db b \int_b^\infty dr \frac{r}{\sqrt{r^2 - b^2}} \epsilon_{E(1+z)}(r), \quad (3)$$

where $\epsilon_E = j_E/E$ is the photon emissivity. The spectral emissivity is $j_E = n_H n_e \Lambda_E(T, Z)$, where n_e and n_H are the electron and hydrogen densities: the temperature T and the metal abundance Z enter j_E only through the spectral cooling function Λ_E . The occurrence of a double integral in the evaluation of a spectrum is a computationally tough problem. The possibility of writing a reasonably efficient *XSPEC* code to model the spectrum of a cluster lies in the possibility of reducing this double integral to a single integral. Under the hypothesis of spherical symmetry this can be done, and the reader is referred to Appendix A for the technical details. The resulting formula

$$\mathcal{F}_E = \frac{4\pi}{D_A^2 (1+z)^2} \int_{b_{\min}}^\infty dr \mathcal{K}(r; b_{\min}, b_{\max}) \epsilon_{E(1+z)}(r) \quad (4)$$

$$\mathcal{K}(r; b_{\min}, b_{\max}) = \begin{cases} r \sqrt{r^2 - b_{\min}^2} & \text{if } r < b_{\max} \\ r \left(\sqrt{r^2 - b_{\min}^2} - \sqrt{r^2 - b_{\max}^2} \right) & \text{if } b_{\max} \leq r \end{cases} \quad (5)$$

is the basis of our deprojection method.

3. THE PROBLEM OF DEPROJECTION

3.1. The geometrical deprojection

The problem of recovering the 3-D shape of T , n_H and Z is usually tackled with the methods of geometrical deprojection. Our term “geometrical” encompasses a variety of non-parametric techniques to extract 3-D quantities from their corresponding 2-D projected counterparts. This Subsection provides a summary of the main geometrical deprojection techniques, as well as some references for further readings on the subject.

The method of deprojection in the study of galaxy clusters was introduced by Fabian et al. (1981), and Kriss, Cioffi & Canizares (1983) in their pioneering works on the analysis of *Einstein* data. The spectral resolution of the instruments *HRI* and *IPC* on board *Einstein* was too poor for a direct deprojection of the spectra, and these authors unfolded the cluster starting from its surface brightness. In the hypothesis of spherical symmetry, the image of the cluster is divided into N rings of radii $r_1 < r_2 < \dots < r_N$ centered on the emission peak. The 3-D emission is supposed to come from N homogeneous spherical shells bounded by the same radii. The observed surface brightness of the j -th projected ring (of area A_j) is

$$S_j = \frac{\sum_{i=j}^N C_i V_{i,j}}{A_j},$$

where $V_{i,j}$ is the volume of the fraction of the i -th spherical shell subtended by the j -th projected ring. This matrix equation can be solved for the spatial count emission rates C_i of each shell. In turn, these quantities are converted to photon emission rates with the effective area

of the instrument. Since the emission rate depends both on temperature and density, in the absence of further spectral information this degeneracy hinders any determination of these quantities. In order to determine separately the 3-D density and temperature profiles, Fabian (1981) was forced to assume an average metallicity of the cluster, and to suppose the gas to be in hydrostatic equilibrium within an *assumed* gravitational potential.

When spectral information became available, the hypothesis of hydrostatic equilibrium could be avoided, thus allowing a substantial extension of this deprojection technique. Nulsen & Böhringer (1995) adopted a variant of Fabian’s method to analyze *ROSAT* spectra: it was applied to the count rate of each energy channel, instead of the integrated spectrum. This procedure yielded the pulse height spectrum of each spherical shell, which was converted to photons and fitted to an emission model to obtain the 3-D values of temperature and hydrogen density.

David et al. (2001) – see also Allen, Ettori & Fabian (2001) and Buote (2000) – modeled the flux from any annulus as a weighted sum of the emissivities of the spherical shells. Each shell was supposed to be characterized by its own uniform temperature, density and metal abundance, considered as the parameters of the fit, determined by fitting simultaneously the annular spectra.

Ettori et al. (2002) devised a matrix method to deproject spectra. The spectrum of each ring is first analyzed to determine its emission weighted projected temperature, metal abundance, emission integral and luminosity

$$\begin{aligned} T_{\text{ring}}(j) &= \frac{\sum_{i=j}^N \epsilon_i V_{i,j} T_i}{\sum_{i=j}^N \epsilon_i V_{i,j}} \\ Z_{\text{ring}}(j) &= \frac{\sum_{i=j}^N \epsilon_i V_{i,j} Z_i}{\sum_{i=j}^N \epsilon_i V_{i,j}} \\ EI_{\text{ring}}(j) &= \sum_{i=j}^N V_{i,j} n_H n_e \\ L_{\text{ring}}(j) &= \sum_{i=j}^N V_{i,j} \epsilon_i, \end{aligned}$$

where $n_e \simeq 1.21 n_H$ is the electron density, $V_{i,j}$ has the same meaning as before, and ϵ_i is the emissivity (in $\text{erg cm}^{-3} \text{s}^{-1}$) of the i -th shell. Since the volumes are known, the previous matrix equations can be solved to yield the 3-D quantities appearing on their right-hand sides.

3.2. The analytical deprojection

Whenever a spectral information is available, the deprojection techniques described in the last Section do not require the introduction of any “theoretical bias” in the 3-D profiles. Nevertheless, the profiles recovered are often rather wiggly. Thus, for many applications they need to be regularized, causing the loss of some information on the fine-grained patterns of the X-ray emitting gas. Another common requirement of all geometrical techniques is the lack of gaps between nearby rings, since they would bar from knowing the exact number of photon counts to subtract and proceed inwards.

In this paper we introduce an alternative approach to deprojection in which this restriction is not necessary,

and where no *a posteriori* regularization is required. The only condition our method does not relax is the hypothesis of spherical symmetry, under which all the relevant deprojection formulae discussed in this paper have been deduced. Our method loses some fine-grained information (exactly as the geometrical techniques do), the difference being that here the loss occurs *before* the deprojection. In our *analytical deprojection* we model the X-ray emission from the cluster, i.e. we *do* introduce a “theoretical bias” by giving to the 3-D distributions of T , n_H and Z known functional forms, dependent on some parameters $a_1, a_2, \dots, a_N$. With Equation (4) we calculate the model spectrum $\mathcal{F}_E[a_1, a_2, \dots, a_N]$ as a function of these parameters, fit it to the observed spectra and determine the best-fit values of $a_1, a_2, \dots, a_N$, fixing the deprojected 3-D distributions of T , n_H and Z . These profiles do not need any regularization, simply because –strictly speaking–ours is *not* a “deprojection”, but a procedure to determine the parameters of smooth 3-D functions which better match the 2-D observed profiles. One might question the strength of the bias introduced by forcing the 3-D distributions to be described by a functional form with a (necessarily) small number of parameters. This important issue shall be discussed in Section 5.

We have implemented our deprojection technique as a new model for the *XSPEC* analysis software package and have christened it *smaug* after the dragon of J.R.R. Tolkien’s tale *The Hobbit*, but the name also stands for **S**pectral **M**odeling **A**nd **U**nfoldi**ng** of **G**alaxy clusters. Given a first guess of the fit parameters $a_1, a_2, \dots, a_N$, *XSPEC* calls *smaug* and calculates for it the spectral cooling function $\Lambda_E(T, Z)$. Then *smaug* sums up the local contributions to the spectrum by evaluating the right-hand side of Equation (4), and passes back the result to *XSPEC*. Finally, *XSPEC* compares the model spectra to the observed spectra and works out an improved estimate of $a_1, a_2, \dots, a_N$. The procedure is iterated until the values of the fit parameters are stable.

The evaluation of the *smaug* model requires the calculation of the integral (4), deduced from the double integral (3) under the hypothesis of spherical symmetry. This reduction is necessary, since double integrals are not easy to evaluate numerically. Besides, the integrand function contains the spectrum $\epsilon_E(r)$, i.e. a function not only of r , but also of the energy E . Without the reduction of the double integral, the evaluation of a model spectrum would be exceedingly time-consuming from the computational viewpoint. Even the numerical calculation of the single integral (4) requires some care in order to keep as light as possible the computational effort without losing accuracy. We have confined all technical considerations about this important topic to Appendix B, and the interested reader is referred there.

The model is fed with a collection of spectra extracted in annuli centered about the X-ray emission peak. Having specified the cosmology, the user is prompted for a series of parameters. The first are the redshift z of the source, the rims $b_{\min}$ and $b_{\max}$ (in arcmin) of each extraction ring, as well as the cutoff radius (in Mpc) and the number of mesh points for the calculation of the integral (4). Two further fixed parameters specify whether the spectrum is to be calculated or interpolated from existing tables, and which type of plasma emission code has to be

used: the choice is among Raymond-Smith, Mekal, Meka, or APEC. The variable fit parameters of the model define the distributions of hydrogen density, electron temperature and metal abundance within the cluster.

The hydrogen density profile is modeled with a double-beta function, fixed by six parameters:

$$n_H(r) = n_0 [f n_c(r) + (1 - f) n_g(r)], \quad (6)$$

where

$$n_{c,g}(r) = \left[1 + \left(\frac{r}{r_{c,g}} \right)^2 \right]^{-\beta_{c,g}}. \quad (7)$$

The first beta-component refers to the ICM, and the second to the dominant galaxy (if any) lying at the center of the cluster. The variable n_0 is the central hydrogen density, and f is the fraction of n_0 relative to the ICM. The rationale for the choice (6) is that double beta-models have been widely and successfully applied to fit the density distributions in several clusters (see e.g. Mohr, Mathiesen & Evrard 1999).

The next group of eight parameters defines the temperature profile

$$\begin{cases} T(r) = k(r) [T_0 + T_1 l(r)] \\ k(r) = [1 + (r/r_{\text{tail}})^2]^{-\omega} \\ l(r) = \frac{2}{\pi} \frac{\arctan[(r/r_{\text{iso}})^{\xi}]}{1 + (r_{\text{cool}}/r)^{\xi}}. \end{cases} \quad (8)$$

Despite its appalling appearance, this formula has a simple astrophysical rationale. There are three regions with characteristic radii r_{iso} , r_{cool} and r_{tail} , the hierarchy of which is expected to be $r_{\text{iso}} < r_{\text{cool}} < r_{\text{tail}}$. At small radii, i.e. for $r \lesssim r_{\text{iso}}$, the plasma is nearly isothermal, being $T \sim T_0$. This core flattening of T has been recently observed with *Chandra* in some clusters (A2199: Johnstone et al. 2002; A1835: Schmidt, Allen & Fabian 2001; A1795: Ettori et al. 2002). At intermediate radii $r_{\text{iso}} \lesssim r \lesssim r_{\text{cool}}$ the temperature $T \sim T_0 + T_1 l(r)$ increases with radius, as observed in practically all relaxed clusters harboring a cD galaxy at their center (see e.g. De Grandi & Molendi 2002). At radii larger than r_{cool} the temperature flattens, and finally for $r \gtrsim r_{\text{tail}}$ it starts to decrease, behaving essentially as a beta function, in the same fashion as the hydrogen density. In the outskirts of the cluster $T \propto r^{-2\omega}$ and $n_H \propto r^{-2\beta_c}$, thus the equation of state of the ICM is expected to be a polytrope $T \propto n_H^{\omega/\beta_c}$. The decrease of T at large radii was first observed by Markevitch et al. (1998) with *ASCA* in a sample of 30 clusters, and more recently by De Grandi & Molendi (2002) with *Beppo-SAX*.

It is worth to remark that an apparently complicated profile like (8) is actually highly modular: by suitably fixing some parameters, the user may impose the temperature profile to be only increasing, only decreasing, or even isothermal. A function like (8) is able to encompass a wide range of qualitative behaviors of the spatial temperature profile.

The metal abundance profile is described by the three parameters function

$$Z(r) = Z_0 \left[1 + \left(\frac{r}{r_Z} \right)^2 \right]^{-\zeta}. \quad (9)$$

This choice is motivated by the observation of a radial decrease in the metal concentration in practically

all clusters (De Grandi & Molendi 2001), and by more recent *Chandra* and *XMM-Newton* observations showing a flattening of the metallicity in the core of M87/Virgo (Molendi & Gastaldello 2001) and other clusters (e.g. A496: Tamura et al. 2001). For the time being we have not included in the functional form of $Z(r)$ the decrease in metallicity observed in the core of Perseus (Schmidt, Fabian & Sanders 2002) and of Centaurus (Sanders & Fabian 2002). If called for by future observation, it will be easy to modify the profile (9) to properly describe this behavior.

It is known that *XSPEC* rescales any additive model by multiplying it for a normalization constant $\mathcal{N}$ (Arnaud & Dorman 2000), thus the model parameter n_0 in Equation (6) is degenerate with respect to $\mathcal{N}$. Before starting a fit, n_0 must be fixed to unity. The normalization $\mathcal{N}$ imposed to *smaug* by *XSPEC* has the meaning of the square of the central hydrogen density in cgs units, so $\mathcal{N}^{1/2} = n_H(r=0) \text{ cm}^{-3}$.

As a final remark, we would like to stress that our model is extremely flexible: the code has been written with a modular structure, allowing an easy change of the functional forms of n_H , T or Z , whenever new and better X-ray observations will require it. For instance, to modify the temperature profile (8), the user has to 1) replace the code fragment returning the temperature with a more suitable one, 2) edit the parameters input section in the main program, and finally 3) edit the `lmodel.dat` *ASCII* file telling *XSPEC* what are the model parameters (Arnaud & Dorman 2000). We hope that the good flexibility might render *smaug* (and its possible future implementations) a useful tool for the whole community.

4. A SPECIFIC EXAMPLE: THE DEPROJECTION OF ABELL 1795

4.1. Data preparation

In this Section we describe how our deprojection code works in practice. We deproject the spectrum of A1795, a nearby ($z = 0.0631$) and relatively relaxed cool-core cluster (Ettori et al. 2002). For our analysis we have taken a flat Universe with $\Omega = 1.0$, $\Omega_\Lambda = 0$, and $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$. In order to cover the whole cluster, we have used the observations of three satellites, namely *Chandra*, *XMM-Newton* and *Beppo-SAX*. Their views are complementary: *Chandra*'s sharp angular resolution (below 1 arcsec, corresponding to 1.7 kpc at the distance of A1795) is optimal for observing the core of the cluster. *XMM-Newton* has a broader PSF, but thanks to its wider field of view and large collecting area is particularly well-suited for observing the intermediate regions. In the outskirts, where *XMM-Newton*'s view is contaminated by a relatively high background and angular resolution is less critical, *Beppo-SAX* is a better choice. It is worth noting that the composite view from these satellites covers about two decades of the cluster extension, ranging from about 10 kpc to 1.5 Mpc.

The 19.5 ks *ACIS-S Chandra* observation has been taken with a focal plane temperature of -110 degrees. The analysis has been performed with version V2.2 of the CIAO software and with the calibration data base CALDB 2.12. The details on the preparation and analysis of the *XMM-Newton* data are the same as in Molendi & Pizzolato (2001), the only difference being that here

the new version V5.2 of the SAS software has been used. The preparation of the data from *Beppo-SAX* is described in De Grandi & Molendi (2001).

In order to check the results of analytical deprojection, we have also undertaken the analysis with Ettori's matrix geometrical method. In the remainder of the paper we shall often address Ettori's method simply as "geometrical deprojection". The reader should remind, however, that this is only one of the possible geometrical deprojection techniques.

4.2. The geometrical deprojection

We have selected 5 spectra from *Chandra*, 4 from *XMM-Newton*, 4 from *Beppo-SAX*, and have accumulated them in concentric rings centered about the X-ray emission peak. They have been analyzed using version 11.0.1 of *XSPEC*. A spectral analysis is common to the geometrical and the analytical deprojection. In the first case the analysis provides the 2-D emission-weighted quantities, still to be deconvolved. In the second, the spectral analysis directly yields the parameters of the 3-D distributions of the relevant physical quantities.

Both spectral analyses include a *wabs* multiplicative component for the Galactic absorption ($1.21 \times 10^{20} \text{ cm}^{-2}$). A variable *constant* factor describes a moderate ($\lesssim 10\%$) cross-normalization uncertainty among *Chandra*, *XMM-Newton* and *Beppo-SAX*. Since the spectra are not simultaneously fitted in the case of geometrical deprojection, the value of these cross-normalization factors must be provided. We have taken their values from the result of the (simultaneous) fit of the spectra performed with the *smaug* model described in the next Section. A further fixed geometrical *constant* factor has been introduced to account for the excision of the portion of the *Beppo-SAX* detectors shaded by the entrance windows. Since geometrical deprojection proceeds inwards, and necessarily only a finite number of rings can be used, the contamination from the emission of the cluster outskirts must be considered. We have modeled this cutoff effect as described by McLaughlin (1999). Table C1 summarizes the radii of the extraction regions of the spectra, their energy ranges, the geometrical corrections and the cross-normalization factors for the 13 datasets employed.

The spectral analysis preliminary to the geometrical deprojection has been performed with a model *wabs*constant*constant*mekal*. The *mekal* component yields the emission integrals and the (projected) emission weighted temperature and metallicity of any ring, from which the relevant 3-D profiles can be extracted as described at the end of Section 3.1. The error on these deprojected profiles is estimated with a Monte Carlo technique. We build a sample of randomly distributed values around the mean, assuming Gaussian errors. From this sample a statistical collection of 1000 2-D profiles is obtained and deprojected: the standard deviation of the deprojected sample provides the required estimate of the error on the 3-D profiles. The outcomes relative to geometrical deprojection are shown by the marks and error bars in Figures C1, C2 and C3. These Figures also plot the analytically deprojected results described in the following Subsection.

4.3. The analytical deprojection

In the language of *XSPEC*, our analytical model is `wabs*constant*constant*smaug`. The meaning of the first three components has already been discussed: *smaug* provides the parameters for the 3-D distributions of hydrogen density, temperature and metal abundance.

The analytical model has 15 free parameters: two cross-normalization constants for the satellites and 13 parameters for *smaug*. We have calculated the X-ray emission from A1795 with the *Mekal* emission code. The cutoff radius and the number of mesh points for the evaluation of the integral (4) have been fixed respectively to 2 Mpc and 15. We have checked *a posteriori* that the best-fit values of the parameters thus determined are not sensitive to these choices. In particular, changing the cutoff radius to 3 Mpc and rescaling the number of mesh points, the values of the best-fit parameters do not change appreciably, indicating that there are no important numerical effects associated with the evaluation of the integral (4).

Not all the parameters available in *smaug* have been employed for the analysis of A1795: like all parametric models, *smaug* calls for some *a posteriori* fine tuning of the parameters, suggested by the results of the fitting procedure. The exponent $\varkappa$ of the temperature gradient at intermediate radii during the fit systematically pegs against its upper hard limit $\varkappa = 10$, where we have chosen to freeze it. For this cluster the temperature distribution does not depend much on the cooling radius r_{cool} , which is rather ill-determined by the fit procedure. Therefore, we have decided to set it equal to the radius of the cluster density beta component r_c . The polytropic index γ of the plasma in the outskirts is poorly constrained by the *Beppo-SAX* datasets, whose statistics is rather poor with respect to *Chandra* and (above all) *XMM-Newton*. For this reason we have fixed its value, taking it from the statistical analysis by De Grandi & Molendi (2002) of the temperature profiles of a sample of *Beppo-SAX* clusters. These authors find an average $\gamma = 1.2$ for cool-core clusters. Accordingly, in our analysis we have fixed $\omega/\beta_c = \gamma - 1 = 0.2$.

The metal profile is a rapidly declining function of the radius, and therefore the parameter Z_0 is rather uncertain. When left free the radius r_Z assumes the unreliably small value of 1 kpc, comparable to the angular size of *Chandra*'s PSF at the distance of A1795. We have therefore frozen r_Z to 8.24 kpc, i.e. one-half of the innermost *Chandra*'s radial bin. The parameter Z_0 assumes the physical meaning of the metallicity of the central bin.

The deprojected profiles of density, temperature and metal abundance are plotted in Figures C1, C2 and C3. The best-fit values of the free parameters are shown in Table C2 with their 1- σ errors. The reduced chi-square of the best fit is $\chi^2/\text{dof} = 3652/3031 \simeq 1.20$, but its associated probability is negligible, only 3.2×10^{-14} . This value is clearly underestimated: indeed, our analysis uses the spectral data from three different satellites, and thus a degree of cross-calibration error is unavoidable. We have partly kept notice of this by introducing two variable constants in our spectral analysis, but this is not good enough, since the spectral fit procedure tends to interpret the systematic cross-calibration differences as statistical errors, thus lowering the probability of the fit. We shall return in Section 5 to the problem of testing an analytical spectral model in presence of this effect.

Like all models characterized by many fitting parameters, also ours may be affected by the problem of secondary minima. A clear example is the rather complex $\Delta\chi^2$ pattern of the exponent β_c relative to the hydrogen density, plotted in the left panel of Figure C4. The absolute minimum is well defined, but the plot is asymmetric, with several secondary minima. Complex behaviors are not always the rule: a much more well-behaved $\Delta\chi^2$ is shown in the right panel of the same Figure, and refers to the temperature exponent ξ . These examples demonstrate that it is always a good practice to check the results against the possibility of secondary minima, before trusting blindly a deprojected profile.

4.4. Inspection of the best fitting spectra

We now turn our attention to the problem of checking the quality of our model for A1795. We have already remarked that in our case the χ^2 test is of relatively little use, being affected by the systematic cross-calibration effects arising from the use of data sets from different satellites. For this reason, in this and the next two Subsections we explore alternative routes.

The first possibility, discussed in this Subsection, is essentially a qualitative examination of the residuals left over by the model on the spectrum of each annulus. Figure C5 plots the spectra of the 13 rings together with the related best fitting models and their residuals, expressed as ratio data/model. As expected, the residuals of *XMM-Newton*'s data are smaller than the others: because of its wide collecting area, *XMM-Newton* strongly dominates the statistics of the whole data set.

The qualitative analysis presented here is easily understood recalling how the physical parameters shape the X-ray spectrum of a thermal plasma. The (squared) hydrogen density provides the overall normalization of the spectrum, the plasma temperature fixes its exponential cut at high energies, and finally the metal abundance gives the equivalent width of a line.

An inaccurate modelization of the n_H profile would appear as a bad overall normalization of the spectrum of one or more annuli. The lower panels in Figure C5 show such an effect in the innermost spectrum, indicating that our model slightly underestimates the central density. The evidence of systematic normalization effects on the outer *Beppo-SAX* annuli is less clear.

The systematic residuals at high energy are fairly small for any data set, showing that the 3-D temperature profile is modeled adequately by our functional form (8).

At the typical temperatures we have determined, the metal contribution mainly stems from iron. The local residuals about the 7 keV Fe-K line and the $\simeq 1$ keV Fe-L blend test the accuracy of the determination of the metal distribution. The Fe-K line has a good statistics only where the cluster is hot enough, i.e. in correspondence of the area covered by *XMM-Newton*. Near the core, where the cluster is cooler, the line emission is dominated by the Fe-L blend. Unfortunately, the Fe-L blend statistics is not high, and *Chandra*'s determinations of the metal abundance are rather scattered, as shown in Figure C3. In the absence of strong constraints from the data, therefore, we conclude that even for the metal distribution our model is fairly reliable.

4.5. Comparing the analytical and geometrical routes: a discussion

A second way to check the goodness of our fit is to compare its results with those from the matrix geometrical deprojection.

The best-fit analytically deprojected 3-D profiles of hydrogen density, temperature and metal abundance are plotted in Figures C1, C2, C3, together with their geometrically derived counterparts. Each of these Figures also shows the 1- σ error band about the best-fit profile. The band enclosing the best-fit curve is the area spanned by all the functions whose parameters yield a difference $\Delta\chi^2 \leq 1$ with respect to the best-fit χ^2 . This method of characterizing the errors is thoroughly described in Appendix C.

Figure C1 shows that our modeled density is smaller than the geometrically deprojected value in the central annulus, and larger in the two outermost rings. Elsewhere the agreement between the two techniques is good. These results agree with the qualitative analysis of the model spectral residuals outlined in the last Subsection. Leaving aside the outermost *Beppo-SAX* annuli, whose statistics may be weak, the combined results of analytical and geometrical deprojection seem to suggest that – at least for A1795 – the density profile is somewhat more peaked than a double beta-model.

It is apparent from Figure C2 that the 3-D temperature suffers a sharp discontinuity at about 37 kpc. This fact was anticipated by the strange behavior of the parameter $\varkappa$ noticed in Section 4.3. It is also evident from the geometrical deprojection, and was already noticed by Ettori et al. (2002) in the same position. We view the ability of our model to spot such an unexpected distribution in the three-dimensional temperature profile positively. Our deprojection finds a maximum 3-D temperature of 5.8 keV, to be compared with 7.2 keV of the geometrical deprojection. This difference is due to discrepancies in the calibration of the satellites. Figure C6 shows that the temperatures measured by *XMM-Newton* seem too low to match well the neighboring values provided by *Chandra* and *Beppo-SAX*. Because of their strong statistical weight, *XMM-Newton*'s measures tend to lower our deprojected profile, reducing also the maximum temperature.

Figure C3 compares the 3-D metal profiles. The agreement between the analytical and the geometrical deprojection is good. In this case it is particularly clear how our profile turns out to be smoother than its wiggly geometrically deprojected counterpart, which would need a regularization in view of deriving other physical quantities.

4.6. Back to Flatland

The third reliability test we suggest is very stringent, since it compares directly the model predictions with the emission weighted, observed quantities. It consists in re-projecting the 3-D best-fit model profiles and comparing them to the 2-D measurements.

The procedure for temperature T and metal abundance Z are the same, so we sketch it for temperature only. The temperature $T_{2D}(b_1, b_2)$ averaged over the volume

seen under the annulus bounded by the rims b_1 and b_2 is

$$T_{2D}(b_1, b_2) = \frac{\int_{b_1}^{b_2} db \int_0^\infty dl j(r) T(r)}{\int_{b_1}^{b_2} db \int_0^\infty dl j(r)},$$

where $j(r)$ is the plasma emissivity. The integrals in dl along the line of sight can be expressed as radial integrals with the geometrical relation $r^2 = l^2 + b^2$. The resulting double integrals (in db and dr) can be reduced to single integrals, as described in Appendix A. The previous formula is therefore

$$T_{2D}(b_1, b_2) = \frac{\int_{b_1}^{b_2} dr \mathcal{K}(r, b_1, b_2) j(r) T(r)}{\int_{b_1}^{b_2} dr \mathcal{K}(r, b_1, b_2) j(r)}, \quad (10)$$

where the kernel $\mathcal{K}$ is given by Equation (5). As long as the temperature of the ICM remains above $\simeq 2$ keV, the contribution from line emission is negligible and the emissivity is mainly due to thermal Bremsstrahlung, yielding $j \propto n_H^2 T^{1/2}$. We calculate the emission weighted quantities under this assumption.

Figure C6 plots the calculated $T_{2D}(b_1, b_2)$ binned over rings 17 kpc wide over the observed values, directly obtained from the *mekal* analysis. Similarly, Figure C7 compares the measured and re-projected metal abundance profiles. In both cases, the results are in good agreement with the observations.

For the re-projection of hydrogen density we have taken a slightly different route. The geometrical deprojection spectral analysis yields the *mekal* normalization of the spectrum of each ring (Arnaud & Dorman 2000)

$$\mathcal{M} = \frac{10^{-14} \int dV n_e n_H}{4\pi D_A^2 (1+z)^2},$$

where the integral is extended over the volume seen through the ring, D_A and z are respectively the angular distance and the redshift of the cluster. From our analytical deprojection the distributions n_H and $n_e \simeq 1.21 n_H$ of hydrogen and electron densities are known, and therefore the quantity $\mathcal{M}$ can be evaluated for each ring, and compared to the corresponding value provided by the *mekal* analysis. Figure C8 shows the results, which again are in good agreement, with the possible exception of the innermost ring.

5. ON THE REJECTION OF AN UNSATISFACTORY MODEL

So far we have devoted a good deal of attention to check the goodness of a single *fit*. In this Section we explore the related issue of how to check the goodness of a *fitting function*. The problem is to assess our ability to reject an unsatisfactory spatial profile. We would like to consider only self-contained tools, which do not require to compare our results with those from other kinds of deprojection.

It is clear that the spectral test and the reprojection test discussed above are well-suited for this goal. A spatial functional form ought to be rejected when it leaves relevant systematic errors on many annular spectra and on the re-projected quantities, and when these residuals cannot be reduced with any choice of the functions parameters. For instance, the reprojection test rules out an isothermal profile for A1795: the projection of a constant function is again a constant function, clearly at odds with the 2-D profile shown in Figure C6. The same

result comes from the spectral test, since the systematic residuals left over by an isothermal profile are large.

Both the reprojection and the spectral test have been devised to complement the χ^2 test when systematic cross-calibration effects due to the use of inhomogeneous data sets are important. Obviously, these effects lessen the reliability of the χ^2 test also in testing the quality of a fitting function. There is an important limit, however, in which the χ^2 test is still extremely useful, namely when the function is *grossly* wrong. In this case, the statistical errors yield a much larger contribution than the systematics, and the χ^2 test is reliable. For instance, had we taken a simple power-law for the n_H distribution, we would have obtained $\chi^2/\text{dof} = 62271/3035 \simeq 20.5$. The badness of the fit is so marked that the value of the χ^2 is only marginally affected by systematic errors, and can be confidently used to rule out such an unlikely profile.

The χ^2 test also rules out both an isothermal, a beta-model and a polytropic profile for the temperature⁴. The reduced chi-squared is $\chi^2/\text{dof} = 4052/3034 \simeq 1.3$ for the isothermal model, $\chi^2/\text{dof} = 3740.6/3031 \simeq 1.2$ for the beta-model and $\chi^2/\text{dof} = 3781.1/3034 \simeq 1.24$ for the polytropic model. These figures are not exceedingly larger than our best-fit value, nevertheless the models can be safely rejected with an F-test, summarized in Table (C3). As a by-product, these tests indicate that models with few parameters cannot reproduce adequately the temperature profile of A1795, and all the free parameters employed to describe our best-fit temperature profile are necessary.

We have also tested the modified double beta-model

$$n_H = n_0 \left\{ f[1 + (r/r_H)^2]^{-\beta_H} + (1 - f)[1 - (r/r_C)^2]^{\beta_C} \right\}. \quad (11)$$

put forward by Ettori (2000) to correct the original double beta-model, which lacks a satisfactory physical meaning.

The rationale of this model is the confinement of the cool gas within the sphere of radius r_C where radiative cooling is important. We have tried several combinations of parameters: letting all them free, linking or freezing some of them, but in any case the corrected double beta-model has somewhat worsened the quality of the fit with respect to the native double beta-model. For instance, by freeing all the density, temperature and metal abundance parameters (with the exception of the metallicity radius r_Z and the temperature exponent α , which is irrelevant to the present discussion), the χ^2 has worsened from $\chi^2/\text{dof} = 3652.3/3031 \simeq 1.20$ (original double-beta), to $\chi^2/\text{dof} = 3785.1/3030 \simeq 1.25$ (corrected double-beta). The best-fit confinement radius $r_C = 180$ kpc is essentially inside the *XMM-Newton* and *Beppo-SAX* datasets, which are therefore described by the hot-beta component alone (the first right-hand term in Equation [11]). In other words, we have given up the degrees of freedom of the cold component to model the most statistically relevant datasets, which of course reflects on the final χ^2 .

The use of the χ^2 test to reject a model gets difficult

⁴ The beta-model for the temperature has been obtained by fixing some parameters in the general profile (8), and corresponds to the function $T = T_0 k(r)$ in the notation of that Equation. The polytropic profile $T \propto n_H^\alpha$ has been obtained with a slight modification of the *smaug* code.

as the model improves, i.e. the functional form is flexible enough to be able to reproduce fairly well the qualitative behavior of the actual 3-D distributions. In this case the role of statistical errors decreases in front of the systematics, which tend to “saturate” the χ^2 , especially when dealing with inhomogeneous data sets. In order to get rid of this effect and focus on testing the reliability of our functional forms, we have analyzed separately *Chandra* and *XMM-Newton* datasets. In both cases the reduced χ^2 diminishes, ($\chi^2/\text{dof} = 1362.5/1098 \simeq 1.24$ for the 5 *Chandra* datasets and $\chi^2/\text{dof} = 1806.2/1535 \simeq 1.18$ for the 4 *XMM-Newton* rings), but the associated probabilities remains small. Since calibration effects are reduced, they are unlikely to be fully responsible for this. This indicates that the introduction of a functional form is certainly an oversimplification of the complexity of a system like a galaxy cluster. It smoothes out local inhomogeneities, deviations from spherical symmetry, and so on. It is clear that if the spectra have good statistics as in the present case, these unmodeled effects reflect on the final value of χ^2 .

We conclude that a bad χ^2 model is not always to be discarded. If it has good reprojection and spectral residuals tests, it should be regarded as a reasonable model for the 3-D structure of a cluster, and may be as useful as a profile obtained via geometrical deprojection. Indeed, the deprojected profiles are usually taken as a starting point for other calculations, like the gravitating mass of the cluster. In a geometrical deprojection one may obtain a good χ^2 statistics on the spectral fits, but the 3-D raw profile often needs smoothing to be used for further analyses. It is clear that smoothing erases *a posteriori* some of the original information. Along the analytical route, some of this information is disregarded *a priori*, at the cost of a relatively high χ^2 . The 3-D profiles, however, are smooth and ready for further uses. Moreover, the knowledge of the functional forms of the distribution in some occasion may prove useful.

To summarize, some warnings are in order: the analytical deprojection is not foolproof: a preliminary analysis of the regions to deproject is necessary to be sure not to miss important details of the structure of the cluster to be analyzed. Moreover, the final fit should never be taken as gospel truth, but always checked against possible flaws in the model or in the functional forms for the spatial distributions of the physical quantities. To this end, the χ^2 test of the results should be used with care, considering the possible role of systematic cross-calibration effects. Generally speaking, our advice is to privilege the spectral and the reprojection tests to check the quality of a fit, as well as of the functional form of a fitting function.

In conclusion, if the analytical method is used carefully, it may provide a reliable deprojection of a galaxy cluster. Further, the knowledge of explicit functional forms for the distributions of density, temperature and metals somewhat simplifies the after-deprojection task of working out indirect quantities like the mass profiles of the cluster, as explained in the next Section.

6. RECOVERING THE MASS PROFILES

In this Section we show how the results obtained from analytical deprojection can be used to deduce the mass profiles of the cluster. This part of the procedure is not

implemented directly in the model *smaug* within *XSPEC*, but it represents an important complement to the information provided by the spectral deprojection. Indeed, it is a sort of *a posteriori* justification of the whole machinery of analytical deprojection. Therefore, the codes necessary to this part of the spatial analysis of a cluster will be made available to the community to complete *smaug*.

Once the profiles of hydrogen density, temperature and metal abundance have been determined, in principle it is easy to recover other interesting physical quantities like the gravitating mass, the X-ray emitting gas mass fraction or the metal mass. This is an advantage of our analytical deprojection: the knowledge *a priori* of the functional forms of n_H , T or Z allows an easy automatization as well as the numerical stability of all the necessary procedures. The hypothesis of hydrostatic equilibrium and the equation of state for the ICM yield the profile of the gravitating mass within radius r :

$$M_g(< r) = -\frac{kT(r)}{G\mu m_p} r \left(\frac{d \log n_H}{d \log r} + \frac{d \log T}{d \log r} \right) \quad (12)$$

(see e.g. Sarazin 1988). The quantities on the right-hand side of Equation (12) can be calculated analytically from the profiles (6) and (8): some lengthy but straightforward algebra yields

$$\begin{aligned} \frac{d \log n_H}{d \log r} &= \frac{-2}{f n_c + (1-f) n_g} \left[\frac{f \beta_c}{1 + (r_c/r)^2} n_c + \frac{(1-f) \beta_g}{1 + (r_g/r)^2} n_g \right] \\ \frac{d \log T}{d \log r} &= \frac{-2\omega}{1 + (r_t/r)^2} + \frac{T_1 l(r)}{T_0 + T_1 l(r)} \times \\ &\left\{ \frac{\varkappa}{\arctan[(r/r_{\text{iso}})^{\varkappa}]} \frac{(r/r_{\text{iso}})^{\varkappa}}{1 + (r/r_{\text{iso}})^{2\varkappa}} + \frac{\xi}{1 + (r/r_{\text{cool}})^{\xi}} \right\}. \end{aligned}$$

In the case of A1795, as we have anticipated, the hypothesis of hydrostatic equilibrium breaks down at about 37 kpc from the center, because of the discontinuity in the temperature profile. Mathematically, in Equation (12) the derivative of T is large and positive, thus making $M_g(< r)$ negative. This is shown in Figure C9 by the plots of the derivative of T and the calculated $M_g(< r)$ profile. It is important to remark that the hydrostatic determination of the gravitating mass only fails near the temperature discontinuity. The physics of this region is complex: according to Markevitch, Vikhlinin & Mazzotta (2001) the cold gas is slowly moving within the gravitational potential of the bulk of the cluster, probably after a past subcluster infall. Elsewhere the hydrostatic condition holds, and this recipe for the determination the gravitational mass is relatively safe. We remark that the ability of our model to spot an unexpected behavior of the gravitating mass ought to be considered an index of its flexibility, rather than a drawback. A simple numerical integration of the hydrogen density (6) provides the mass profile of the X-ray emitting gas enclosed within the radius r :

$$M_X(< r) \simeq 1.39 m_p \int_0^r 4\pi dr' r'^2 n_H(r'), \quad (13)$$

where the factor 1.39 is the correction from the hydrogen to the average ion density. This mass profile is defined by an integral, thus it is always well defined, unlike

the gravitating mass, whose determination relies on the derivatives of potentially bad-behaved functions, as happens for A1795. Figure C10 shows the X-ray emitting gas fraction $f(< r) = M_X(< r)/M_g(< r)$. It reaches a plateau of about 0.17, but slightly rises in the outskirts. This final trend (which is nevertheless consistent at the 2- σ level with being a constant) is related to the possible overestimate of the hydrogen density profile at large radii previously noticed. This leads to overestimate the gas mass profile $M_X(< r)$, and hence the fraction $f(< r) = M_X(< r)/M_g(< r)$.

The combination of the hydrogen and metallicity profiles provides the metal distribution. At the temperatures observed in A1795, the main contribution to the metallicity profile $Z(r)$ comes from iron, the concentration of which is approximately

$$n_{\text{Fe}}(r) \simeq [\text{Fe}/\text{H}] n_{\text{H}}(r) Z(r), \quad (14)$$

where $[\text{Fe}/\text{H}] = 4.68 \times 10^{-5}$ is the solar abundance of iron with respect to hydrogen, according to Anders & Grevesse (see Arnaud & Dorman 2000 and references therein). From n_{Fe} it is easy to deduce the enclosed iron mass $M_{\text{Fe}}(< r)$. Figure C11 plots these quantities.

7. SUMMARY

In this paper we have described a new technique for recovering the three-dimensional structure of clusters of galaxies. The spectrum of a cluster is modeled as a function of a number of parameters, whose values are determined by fitting the model to the observed spectrum. This model can be made to work sufficiently fast as a subroutine of *XSPEC* because the calculation of the spectral model calls for the evaluation of a single rather than a double integral (Section 2 and Appendix A), and because a further analysis has shown that a time-consuming evaluation of the spectral emission function at several points throughout the cluster is unnecessary (Appendix B).

The parameters of the model define the known analytical functions of the spatial distributions of hydrogen density, metal abundance and temperature. From these quantities, under suitable assumptions it is straightforward to obtain other physical quantities like the gravitating mass, the X-ray emitting gas fraction or the distribution of metals within the cluster.

The distinctive feature of this technique is the possibility of adopting known analytical fitting functions for the use of deprojected data. After the spectral analysis, no further work is required to obtain and regularize the three-dimensional profiles. Noticeably, our method has a relatively simple way to characterize the uncertainty of the results (Appendix C), and does not require a Monte Carlo technique. The use of known functions simplifies the reconstruction of the cluster 3-D structure after the spectral deprojection. Once the best-fit parameters have been worked out from the spectra –with all the caveats outlined in Section 5– this part of the procedure can be easily and safely automatized.

We have shown that the functional forms of n_H , T and Z , if suitably chosen, may encompass a wide range of possible behaviors of the profiles of these physical quantities. This was shown by the ability of our model to spot a discontinuity in the temperature profile of A1795. If the data from the last generation of X-ray satellites required it, however, it would be extremely simple to modify these

functional forms to achieve a closer agreement with new observations.

Finally, we have shown that the χ^2 test, the reprojection test and the analysis of the spectral residuals left by the models are useful tools to check the reliability of the results, and possibly may suggest new and better functional forms for the 3-D distributions of density, temperature and metals.

In conclusion, we believe that our deprojection tech-

nique may provide a valid and useful alternative tool for the deprojection of galaxy clusters.

The authors wish to thank Keith Arnaud and Ben Dorman at HEASARC for their prompt and kind guide through the mysteries of *XSPEC*. Thanks also to our referee Stefano Ettori, whose suggestions greatly improved the original manuscript.

APPENDIX

REDUCTION OF THE DOUBLE INTEGRAL

In this Appendix we derive Equation (4) of the text, starting from Equation (1). The integral therein is extended over the solid angle subtended by an annulus bounded by the rims $b_{\min}$ and $b_{\max}$. First make the change of variable from the solid angle to the projected radius $d\Omega = 2\pi b db / D_A^2$, where D_A is the angular distance of the source. Then substitute Equation (2) into (1), taking into account the invariance law $I_{E'}/E'^3 = I_E/E^3$ for the specific intensity. The result is the photon flux seen by the observer

$$\mathcal{F}_E = \frac{4\pi}{D_A^2 (1+z)^2} \int_{b_{\min}}^{b_{\max}} db b \int_b^\infty dr \frac{r}{\sqrt{r^2 - b^2}} \epsilon_{E'}(r), \quad (\text{A1})$$

where the quantity $\epsilon_{E'} = j_{E'}/E'$ is the photon emissivity at the source, in $\text{photons cm}^{-3} \text{s}^{-1} \text{keV}^{-1}$. The primes indicate that the energy with respect to the source and the observer's rest frame differ for the redshift factor $1+z$. The integral in (A1) can actually be reduced to a single integral. By inserting a couple of theta functions

$$\theta(x) = \begin{cases} 0 & \text{for } x < 0 \\ 1 & \text{for } x > 0 \end{cases},$$

the double integral reads

$$\int_{b_{\min}}^{b_{\max}} db b \int_0^\infty dr \epsilon_{E'}(r) \frac{r}{\sqrt{r^2 - b^2}} \theta(r-b) \theta(r-b_{\min}),$$

where the order of integration can be reversed; the integral in db can then be explicitly solved, yielding

$$\int_{b_{\min}}^{b_{\max}} db b \frac{1}{\sqrt{r^2 - b^2}} \theta(r-b) \theta(r-b_{\min}) = \begin{cases} (r^2 - b_{\min}^2)^{1/2} & \text{for } r < b_{\max} \\ (r^2 - b_{\min}^2)^{1/2} - (r^2 - b_{\max}^2)^{1/2} & \text{for } b_{\max} < r \end{cases}$$

On substituting this in the integral over dr , formula (4) of the text is recovered, QED.

NUMERICAL EVALUATION OF THE SPECTRUM

This Appendix provides some technical details about the numerical calculation of the integral in Equation (4) of the text. It is useful to single out the hydrogen density in the emissivity function:

$$\epsilon_E = \frac{j_E}{E} = n_e n_H \frac{\Lambda_E(T, Z)}{E} \equiv n_H^2 \lambda_E(T, Z).$$

Omitting irrelevant factors, the integral to be calculated is

$$\mathcal{F}_E = \int_{b_{\min}}^\infty dr \frac{d\phi}{dr} \lambda_E(T, Z), \quad (\text{B1})$$

where the differential emission integral

$$\frac{d\phi}{dr} = \mathcal{K}(r; b_{\min}, b_{\max}) n_H^2(r),$$

is far more sensitive to the radius r than the spectral function $\lambda_E(T, Z)$, which depends implicitly on r through the functions $T(r)$ and $Z(r)$. This suggests to split the integration interval in several isothermal shells with homogeneous metallicity. Therefore, in each shell the function $\lambda_E(T, Z)$ needs only one evaluation. A high numerical accuracy is put only in evaluating the emission integral of the shell. This approach greatly reduces the (computationally heavy) evaluation of $\lambda_E(T, Z)$ in several mesh points, but preserves the accuracy of the results.

The range of integration is cut-off with the introduction of a user-defined maximum radius $r_{\max}$, typically in the order of $\simeq 2$ Mpc, and the interval $[b_{\min}, r_{\max}]$ is split into N shells bounded by the nodes $r_0, r_1, \dots, r_N$ (in general not evenly spaced); the extremes r_0 and r_N coincide with $b_{\min}$ and $r_{\max}$ respectively. Equation (B1) is rewritten as

$$\begin{cases} \mathcal{F}_E = \sum_{i=1}^N \phi(i) \overline{\lambda_E(i)} \\ \phi(i) = \int_{r_{i-1}}^{r_i} dr \frac{d\phi}{dr} \end{cases}, \quad (\text{B2})$$

where the average spectral function $\overline{\lambda_E(i)}$ over the i -th emitting shell is *defined* as

$$\overline{\lambda_E(i)} = \frac{\int_{r_{i-1}}^{r_i} dr \frac{d\phi}{dr} \lambda_E}{\phi(i)}. \quad (\text{B3})$$

Up to now the equation are *exact*: the approximations are to be introduced now in the evaluation of the average spectral function $\overline{\lambda_E}$. For the sake of readability of the formulae we drop both the spectral index E and the label of the volumes. In Equation (B3) we expand $\lambda(T, Z)$ in a neighborhood of the (still undefined) average temperature and metallicity $\overline{T}$ and $\overline{Z}$, defined on each shell:

$$\lambda(T, Z) = \lambda(\overline{T}, \overline{Z}) + \frac{\partial \lambda}{\partial T}(T - \overline{T}) + \frac{\partial \lambda}{\partial Z}(Z - \overline{Z}) + \mathcal{O}^2.$$

The term $\mathcal{O}^2$ denotes higher-order terms in $(T - \overline{T})$ and $(Z - \overline{Z})$. If we put this expansion in the right-hand side of (B3) we obtain

$$\overline{\lambda} = \lambda(\overline{T}, \overline{Z}) + \frac{\partial \lambda}{\partial T} \left[\frac{\int dr \frac{d\phi}{dr} T}{\phi} - \overline{T} \right] + \frac{\partial \lambda}{\partial Z} \left[\frac{\int dr \frac{d\phi}{dr} Z}{\phi} - \overline{Z} \right] + \mathcal{O}^2. \quad (\text{B4})$$

If we define the shell averages $\overline{T}$ and $\overline{Z}$ as

$$\overline{T} \equiv \frac{\int dr \frac{d\phi}{dr} T}{\phi} \quad (\text{B5})$$

$$\overline{Z} \equiv \frac{\int dr \frac{d\phi}{dr} Z}{\phi}, \quad (\text{B6})$$

we find $\overline{\lambda} = \lambda(\overline{T}, \overline{Z}) + \mathcal{O}^2$, i.e. the (approximated) spectral function evaluated in $\overline{T}$ and $\overline{Z}$ is first-order accurate with respect to the (exact) spectral function (B3), emission-weighted within a shell.

The trapezoidal rule is accurate enough for the calculation of the integrals in the definitions (B5) and (B6): on the shell $[r_i, r_{i-1}]$, for instance

$$\overline{T}_i \simeq \frac{\mathcal{K}(i) n_H^2(i) T(i) + \mathcal{K}(i) n_H^2(i-1) T(i-1)}{\mathcal{K}(i) n_H^2(i) + \mathcal{K}(i-1) n_H^2(i-1)},$$

where $\mathcal{K}(i)$, $T(i)$, and $n_H(i)$ denote the values of the functions $\mathcal{K}$, T , and n_H evaluated at r_i . As mentioned before, the evaluation of the emission integral $\phi(i)$ in the sum (B2) calls for more accuracy, and therefore we adopt a 10-point Gauss-Legendre formula (see e.g. Press et al. 1992). In each integration shell the differential emission integral is calculated 10 times, which is accurate and relatively fast; the evaluation of the spectral function $\lambda_E(T, Z)$, which is substantially slower, occurs only once.

A final remark is in order about the spacing of the integration nodes $r_0, r_1, \dots, r_N$. Since the differential emission integral usually strongly peaks at $r \lesssim b_{\text{max}}$, we have chosen a quadratically spaced grid, which yields a better accuracy than an evenly spaced one.

ON THE CHARACTERIZATION OF THE ERRORS

In this Appendix we sketch our method to characterize the error on a function $f(r; \mathbf{a})$ dependent on the radial coordinate r as well as on the N parameters $\mathbf{a} = (a_1, \dots, a_N)$. Our problem is to show how their uncertainties reflect on the function f . We start by considering the Taylor expansion of the χ^2 about the best-fit values of the parameters $\tilde{\mathbf{a}} = (\tilde{a}_1, \dots, \tilde{a}_N)$. Here χ^2 has a minimum, and its expansion to the lowest order reads

$$\Delta\chi^2 \equiv \chi^2(\mathbf{a}) - \chi^2(\tilde{\mathbf{a}}) = \frac{1}{2} \sum_{i,k=1}^N (a - \tilde{a})_i (a - \tilde{a})_k \frac{\partial^2 \chi^2(\tilde{\mathbf{a}})}{\partial a_i \partial a_k}. \quad (\text{C1})$$

In the same fashion, the first-order Taylor expansion of $f(r; \mathbf{a})$ about $\tilde{\mathbf{a}}$ reads

$$\Delta f \equiv f(r; \mathbf{a}) - f(r; \tilde{\mathbf{a}}) = \sum_{i=1}^N (a - \tilde{a})_i \frac{\partial f(r; \tilde{\mathbf{a}})}{\partial a_i}. \quad (\text{C2})$$

In what follows we assume that r is fixed, and focus our attention on the N -dimensional parameter space. Here the manifold $\Delta\chi^2 = \text{constant}$ is the $(N - 1)$ -dimensional surface $\mathcal{H}$ of an ellipsoid. In the same space, Equation (C2) defines a family $\mathcal{P}$ of parallel planes dependent on the intercept Δf . The intersection set $\mathcal{H} \cap \mathcal{P}$ contains the parameters which for the assigned value of $\Delta\chi^2$ give the absolute difference $|\Delta f|$ with respect to the best-fit determination of f . If $|\Delta f|$ is large, the intersection is empty: the error on f is too large to be consistent with the given $\Delta\chi^2$. On the other hand, if $|\Delta f|$ is small, there are infinitely many points in the intersection, i.e. several combinations of parameters are able to define many functions characterized by the same $\Delta\chi^2$. It should be clear (and may be proved rigorously) that the largest value of $|\Delta f|$ compatible with the fixed value of $\Delta\chi^2$ occurs for the values $\mathbf{q}$ of the parameters for which

the ellipsoid (C1) and one plane of the family (C2) are tangent. Quite generally, given a point T of coordinates $\mathbf{q}$ lying on the surface $\Delta\chi^2 = \text{constant}$ of the ellipsoid (C1), the plane tangent to the ellipsoid at T is

$$\sum_{i,k=1}^N (\mathcal{E}^{-1})_{ik} (q - \tilde{a})_i (a - \tilde{a})_k = \Delta\chi^2, \quad (\text{C3})$$

where the error matrix $\mathcal{E}_{ik}$ is the inverse of the matrix defined by

$$(\mathcal{E}^{-1})_{ik} = \frac{1}{2} \frac{\partial^2 \chi^2(\tilde{\mathbf{a}})}{\partial a_i \partial a_k}.$$

The tangent plane (C3) at T coincides with the plane of the family (C2) passing through T if the coefficients of both are proportional to each other. This condition yields

$$\Delta f^2 = \Delta\chi^2 \sum_{i,k=1}^N \mathcal{E}_{ik} \frac{\partial f}{\partial a_i} \frac{\partial f}{\partial a_k}. \quad (\text{C4})$$

Since $\mathcal{E}$ is the reciprocal of a (symmetrical) Hessian matrix evaluated at a local (and hopefully, absolute) minimum of χ^2 , it is symmetrical and positive definite; the equation for Δf has two roots $\pm|\Delta f|$. As the radial coordinate r varies, $f(r) \pm \Delta f(r)$ draws the error band associated with the given value of $\Delta\chi^2$.

Alternatively, formula (C4) can be obtained by maximizing the value of $|\Delta f|$ (as a function of the parameters $\mathbf{a}$), subjected to the condition that $\mathbf{a}$ belongs to the assigned manifold $\Delta\chi^2 = \text{constant}$. An application of the standard Lagrange multipliers technique leads again to Equation (C4).

In Equation (C4) the components of $\nabla_{\mathbf{a}} f(r; \tilde{\mathbf{a}})$ are known from the functional form of f and from the best-fit values of the parameters. The matrix $\mathcal{E}$ is *not* directly known, but it can be worked out using the variances and the principal axes returned by *XSPEC* at the end of the fit procedure. The orthogonal matrix $\mathcal{V}$ of the principal axes is made up by the (row) eigenvectors of $\mathcal{E}$, and the variances are the corresponding eigenvalues. Therefore, $\mathcal{E}$ is given by $\mathcal{E} = {}^t\mathcal{V}\Sigma\mathcal{V}$, where Σ is the matrix with the variances on its main diagonal, and ${}^t\mathcal{V}$ is the transpose matrix of $\mathcal{V}$ (the interested reader is referred to any textbook of linear algebra, e.g. Lang 1966).

The next degree of complication occurs when more than one function is present, as it is our case (the reader is reminded that we determine simultaneously the functions n_H , T and Z). Suppose that besides f there is another function g : for instance f and g could be the temperature and the hydrogen density. In order to avoid unnecessary complications, suppose that each function depends only on the radius r and on one parameter: $f = f(r, a)$ and $g = g(r, b)$. The parameter space is the two-dimensional plane ab , the error matrix has rank 2, the χ^2 depends both on a and on b and the surface $\Delta\chi^2 = \text{constant}$ is an ellipse in the plane ab . Assume for the moment that a and b are mutually independent, i.e. they are not linked to each other in the fitting procedure: notice however that this by no means entails they are statistically uncorrelated. As the parameter a varies about its best fit value $\tilde{a}$, the error Δf also varies, and in the same fashion as before its largest value

$$\Delta f^2 = \Delta\chi^2 \mathcal{E}_{11} \left(\frac{\partial f}{\partial a} \right)^2 \quad (\text{C5})$$

occurs where the error ellipse and the line

$$\Delta f = \left. \frac{\partial f}{\partial a} \right|_{a=\tilde{a}} (a - \tilde{a})$$

are tangent. Similarly, the error on g is

$$\Delta g^2 = \Delta\chi^2 \mathcal{E}_{22} \left(\frac{\partial g}{\partial b} \right)^2. \quad (\text{C6})$$

It might be objected that this procedure does not take into proper account a possible statistical correlation between a and b . This is expressed by the off-diagonal terms of the error matrix, that however do not appear in formulae (C5) and (C6). This objection is incorrect, since the correlation between a and b (if any) intervenes also through the diagonal terms $\mathcal{E}_{11}$ and $\mathcal{E}_{22}$. Indeed, the correlation introduces a tilt in the principal axes of the error ellipse with respect to the coordinate axes of the parameter plane. Therefore the diagonal terms of the error matrix in Equations (C5) and (C6) differ in the cases of correlation or uncorrelation between the fit parameters a and b . We may conclude that the errors Δf and Δg are correctly calculated in both cases.

The situation is slightly more complicated if an explicit link $b = \phi(a)$ is introduced in the fit between a and b ; b is no more a free fit parameter, and its role is taken over by a . Because of the link, the quantity $\partial g / \partial a$ does not vanish, since

$$\frac{\partial g}{\partial a} = \frac{\partial g}{\partial b} \phi'(a). \quad (\text{C7})$$

The formula (C6) in this case is replaced by

$$\Delta g^2 = \Delta\chi^2 \left\{ \mathcal{E}_{11} \left(\frac{\partial g}{\partial b} \phi' \right)^2 + 2 \mathcal{E}_{12} \frac{\partial g}{\partial b} \phi' + \mathcal{E}_{22} \left(\frac{\partial g}{\partial b} \right)^2 \right\}. \quad (\text{C8})$$

This procedure of dealing with the links between parameters allows to derive the error for one special parameter, namely the hydrogen central density n_0 of the model *smaug*. n_0 is special because during the fit it is *formally* fixed, but its role is played by the normalization $\mathcal{N}$ of *smaug*, being $\mathcal{N} = n_0^2$. We interpret this relation as a formal link $n_0 = \phi(\mathcal{N}) = \sqrt{\mathcal{N}}$ between $\mathcal{N}$ and n_0 . In Equation (C4), the derivative with respect to the fit parameter $\mathcal{N}$ of a function f dependent on n_0 reads

$$\frac{\partial f}{\partial \mathcal{N}} = \frac{\partial f}{\partial n_0} \frac{\partial n_0}{\partial \mathcal{N}} = \frac{1}{2\mathcal{N}} \frac{\partial f}{\partial n_0}. \quad (\text{C9})$$

As a final point, let us consider how it is possible to characterize the error of a function $h = h(f(r, a), g(r, b))$ dependent both on f and g : for instance, if f and g are the temperature and the hydrogen density $h = f g$ is the pressure. The basic formula is always (C4), and therefore it is only necessary to evaluate correctly the derivatives on its right hand side. If the fit parameters a and b are not linked, it is $\partial h / \partial a = (\partial h / \partial f)(\partial f / \partial a)$ and $\partial h / \partial b = (\partial h / \partial g)(\partial g / \partial b)$. The occurrence of a link $b = \phi(a)$ leads to

$$\frac{\partial h}{\partial a} = \frac{\partial h}{\partial f} \frac{\partial f}{\partial a} + \frac{\partial h}{\partial g} \frac{\partial g}{\partial b} \phi'(a). \quad (\text{C10})$$

FIG. C1.— Upper panel: the deprojected hydrogen density profile. The central continuous curve is the best-fit profile yielded by our analytical deprojection with the double beta-function (see Equation [6]). The other curves are the upper and lower boundaries corresponding to a one-sigma error in the parameters (see text). The markers show the data and error bars from Ettori's matrix geometrical deprojection. Circles correspond to *Chandra* data, triangles to *XMM-Newton* and diamonds to *Beppo-SAX*. Lower panel : the ratio between the hydrogen density derived from the geometrical and the analytical deprojection.

FIG. C2.— Upper panel: the deprojected temperature profile, whose functional form is given by Equation (8). The meaning of the symbols is the same as in Figure C1. Lower panel : the ratio between the temperature derived from the geometrical and the analytical deprojection.

FIG. C3.— Upper panel: the deprojected metal abundance profile, with functional form (9). The meaning of the symbols is the same as in Figures C1 and C2. Lower panel : the ratio between the metal abundance derived from the geometrical and the analytical deprojection.

FIG. C4.— The $\Delta\chi^2$ on two fit parameters, obtained by running the *XSPEC* command *steppar*. Left panel: the $\Delta\chi^2$ on the exponent β_c of the hydrogen cluster component. Despite the presence of secondary minima, the best-fit value of this parameter is robust. Right panel: the same plot for the exponent ξ of the temperature profile shows a much smoother behavior.

TABLE C1. EXTRACTION REGIONS FOR THE SPECTRA

Instrument	Cross normalization	Spectral range [keV]	Inner ring [arcsec]	Outer ring [arcsec]	Shading factor
<i>Chandra</i>	106%	0.5–7.0	0	10	1.000
		0.5–7.0	10	25	1.000
		1.0–7.0	25	40	1.000
		1.0–7.0	40	60	1.000
		1.0–7.0	60	90	1.000
<i>XMM-Newton</i>	100%	1.0–10.0	60	120	1.000
		1.0–10.0	120	180	1.000
		1.0–10.0	180	240	1.000
		1.0–10.0	240	300	0.981
<i>Beppo-SAX</i>	95%	2.0–10.0	240	360	1.000
		2.0–10.0	360	480	0.981
		3.5–10.0	480	720	1.000
		2.0–8.0	720	960	0.794

Note. — The cross-normalization constants among the instruments are free parameters of the model. The value relative to *XMM-Newton* is taken as unity by definition. The shading factor takes into account the reduced area of the extraction region of two *Beppo-SAX* spectra due to the entrance window.

TABLE C2. RESULTS FOR THE *smaug* MODEL.

Free parameter	Best-fit value	One-sigma error	Units
f	4.41×10^{-2}	1.40×10^{-2}	—
n_0	2.89×10^{-2}	8.91×10^{-4}	cm^{-3}
β_c	1.76	7.26×10^{-1}	—
r_c	5.03×10^{-1}	1.58×10^{-1}	Mpc
β_g	8.76×10^{-1}	5.72×10^{-2}	—
r_g	5.07×10^{-2}	2.40×10^{-3}	Mpc
Z_0	1.35	1.34×10^{-1}	solar
ζ	2.05×10^{-1}	1.60×10^{-2}	—
T_0	2.85	1.27×10^{-1}	keV
T_1	6.55	6.20×10^{-1}	keV
r_{iso}	3.75×10^{-2}	3.37×10^{-3}	Mpc
ξ	3.94×10^{-1}	9.13×10^{-2}	—
r_{tail}	1.26	5.80×10^{-1}	Mpc

Note. — The parameters not listed are the column density of Galactic absorption $n_H = 1.21 \times 10^{-22} \text{ cm}^{-2}$, κ frozen to 10, r_Z frozen to 8.24 kpc i.e. one-half of the innermost radial bin, r_{cool} (set equal to r_c) and $\omega = 0.2\beta_c$.

FIG. C5.— For any ring, the best-fit spectrum plotted over the data (upper panels). The lower panels show the residuals of the model, plotted as ratio data/model. Panels 1-5 refer to *Chandra*, 6-9 to *XMM-Newton* and 10-13 to *Beppo-SAX*.

FIG. C6.— Upper panel: the re-projected temperature profile plotted over the corresponding 2-D measures provided by the *mekal* analysis. Lower panel: the ratio between the measured emission-weighted temperature and the corresponding re-projected values.

TABLE C3. CHECKING THE TEMPERATURE DISTRIBUTION.

Profile	Free parameters	χ^2	Degrees of freedom	F-test statistic value
isothermal	T_0	4050.8	3035	82.7
beta law	T_0 r_{tail} ω	3731.1	3033	32.7
polytropic	$\dagger$	3781.1	3034	35.6
best-fit	T_0 T_1 r_{iso} ξ r_{tail}	3652.3	3031	—

Note. — The number of free parameters required to describe correctly the temperature distribution. In the beta-model the exponent is free. The F-test statistic values compare the model of each line with respect to the best-fit one. In the row of the polytropic temperature model the names of the free parameters have not been reported, since the function (8) has been modified. In this case, the temperature 3-D distribution is described by two parameters. In all cases the associated probability is well below 10^{-10} , and has not been reported.

FIG. C7.— Upper panel: the re-projected metallicity profile plotted over the corresponding 2-D measures. Lower panel: the ratio between the measured emission-weighted metal abundance and the corresponding re-projected values.

FIG. C8.— Upper panel: The re-projected profile of the emission integral $EI = \int dV n_e n_H$ plotted over its corresponding 2-D measured counterpart. In the y axis $D_A = 3.4 \times 10^2$ Mpc and $z = 0.0631$ are respectively the angular distance and the redshift of A1795. As before, circles indicates *Chandra* data, triangles *XMM-Newton* data and diamonds *Beppo-SAX* data. The observed quantities stem directly from the normalization of the spectra yielded by the *mekal* analysis. The re-projected quantities have been calculated by evaluating numerically the emission integral from the best-fit hydrogen density profile. Lower panel: The ratio between the *mekal* emission integral and our reprojected value.

FIG. C9.— The gravitating mass calculated with Equation (12) (upper panel). Because of the discontinuity edge in the temperature profile, the hypothesis of hydrostatic equilibrium breaks down at $\simeq 37$ kpc. This is best appreciated in the lower panel where we report the logarithmic derivative of the temperature profile.

FIG. C10.— The X-ray emitting gas fraction within radius r is the ratio of the masses given by (13) and (12). The plot excludes the innermost region, where the hydrostatic equilibrium fails. The slight rise in the outskirts is statistically significant only at the $1\text{-}\sigma$ level, as discussed in Section 6.

FIG. C11.— The iron density (upper panel) and the enclosed iron mass within radius r (lower panel). The error curves correspond to $1\text{-}\sigma$ uncertainty in the parameters, and have been calculated as explained in the text (Appendix C).
